Vector constants of the motion and orbits in the Coulomb/Kepler problem

Gerardo Muñoz

Abstract

The equation for the conic sections describing the possible orbits in a potential $V \sim r^{-1}$ is obtained by means of a vector constant of the motion differing from the traditional Laplace-Runge-Lenz vector.

The Laplace-Runge-Lenz[1,2,3,4] (or Hermann-Bernoulli-Laplace[5]) vector provides a simple and elegant way of obtaining the equation for the orbit of a particle moving under the influence of a radial inverse-square-law force.[6] This method also has the added advantage over the more common approach of direct integration of the equations of motion[7] that the very existence of this single-valued constant of the motion explains the otherwise surprising degeneracy of the Coulomb/Kepler problem.[8] Our aim here is to show that there is another vector constant of the motion which makes a first principles derivation of the equation of the orbit even easier than the Laplace-Runge-Lenz vector or the direct integration methods.

The force law $\mathbf{F} = -k\hat{\mathbf{r}}/r^2$ (we assume $k > 0$; the repulsive case may be treated along the same lines) leads to the nonrelativistic equation of motion

$$\frac{d\mathbf{p}}{dt} = -k\frac{\hat{\mathbf{r}}}{r^2}, \tag{1}$$

and to the well-known conservation laws for energy $E = \frac{1}{2}mv^2 - k/r$ and angular momentum $\mathbf{L} = \mathbf{r} \times \mathbf{p}$. If we choose polar coordinates in the plane of the orbit, we have the usual expression $L = mr^2\dot{\theta}$, and also

$$\frac{d\mathbf{p}}{dt} = m\frac{d\mathbf{v}}{d\theta}\dot{\theta} = \frac{d\mathbf{v}}{d\theta}\frac{L}{r^2}\,. \tag{2}$$

Combining Eq. (2) with Eq. (1) we obtain

$$\frac{d\mathbf{v}}{d\theta} = -\frac{k}{L}\hat{\mathbf{r}}\,. \tag{3}$$

Note that Eq. (3) implies immediately that $\mathbf{v}(0) = \mathbf{v}(2\pi)$ and that the velocity vector traces out a circle if θ is allowed to vary from 0 to 2π. Integration of Eq. (3) is trivial if we recall that $d\hat{\boldsymbol{\theta}}/d\theta = -\hat{\mathbf{r}}$:

$$\mathbf{v} - \frac{k}{L}\hat{\boldsymbol{\theta}} = \mathbf{u}\,, \tag{4}$$

where $\mathbf{u}$ is a constant vector. This vector is the constant of the motion we propose to use instead of the Laplace-Runge-Lenz vector in the derivation of the orbits. It is interesting to note that a quaternion equivalent to Eq. (4) was already known to Hamilton in 1845.[9] Unfortunately, this simple result seems to have vanished from textbooks on classical mechanics after the first decade of the twentieth century.[10]

The vector $\mathbf{u}$ may be evaluated in terms of the physical parameters of the problem. If we choose the angle so that the minimum value of r is at $\theta = 0$ and adjust our coordinate

system so that $\mathbf{v} = v_0\hat{\mathbf{y}}$ at $r_{\min}$, we have

$$\mathbf{u} = (v_0 - \frac{k}{L})\hat{\mathbf{y}}\,. \tag{5}$$

Because $L = mr_{\min}v_0$, the energy is $E = \frac{1}{2}mv_0^2 - k/r_{\min} = \frac{1}{2}mv_0^2 - kmv_0/L$. We solve this equation for v_0 and obtain

$$v_0 = \frac{k}{L} \pm \sqrt{\left(\frac{k}{L}\right)^2 + \frac{2E}{m}} = \frac{k}{L}(1 \pm \epsilon)\,, \tag{6}$$

where $\epsilon = \sqrt{1 + 2EL^2/mk^2}$ will turn out to be the eccentricity. The plus sign is required at $r_{\min}$; substituting this result into Eq. (5) provides us with an alternative form for $\mathbf{u}$:

$$\mathbf{u} = \frac{k}{L}\epsilon\hat{\mathbf{y}}\,. \tag{7}$$

Obtaining the equation of the orbit is now straightforward. By taking the scalar product of Eq. (4) with $\hat{\boldsymbol{\theta}}$ and using $\mathbf{v}\cdot\hat{\boldsymbol{\theta}} = r\dot{\theta} = L/mr$, $\hat{\mathbf{y}}\cdot\hat{\boldsymbol{\theta}} = \cos\theta$, we find

$$\frac{L}{mr} - \frac{k}{L} = \frac{k}{L}\epsilon\cos\theta\,. \tag{8}$$

The definition $\alpha = L^2/mk$ allows us to write the solution for r as

$$r = \frac{\alpha}{1 + \epsilon\cos\theta}\,, \tag{9}$$

which is the usual equation of a conic section with one focus at the origin and eccentricity ϵ. Note that the velocity $\mathbf{v} = k[\epsilon\sin\theta\hat{\mathbf{r}} + (1 + \epsilon\cos\theta)\hat{\boldsymbol{\theta}}]/L = k[-\sin\theta\hat{\mathbf{x}} + (\epsilon + \cos\theta)\hat{\boldsymbol{y}}]/L$ follows almost trivially from Eqs. (4) and (7). Hence the orbit in *velocity space* is always circular and characterized by $v_x^2 + (v_y - k\epsilon/L)^2 = k^2/L^2$. More precisely, the orbit in velocity space is a circle of radius k/L and center at $(0, k\epsilon/L)$ if the orbit in position space is a circle ($\epsilon = 0$), an ellipse ($0 < \epsilon < 1$), or a parabola ($\epsilon = 1$). On the other hand, if the spatial trajectory is a hyperbola ($\epsilon > 1$), the angle ranges from $-\cos^{-1}(-1/\epsilon)$ to $\cos^{-1}(-1/\epsilon)$ only, and the velocity space orbit is a section of a circle in the upper v_x, v_y plane with $k(\epsilon^2 - 1)/\epsilon L < v_y \leq k(\epsilon + 1)/L$.

The vector constant of the motion $\mathbf{u}$ is simpler (and its derivation certainly easier[11]) than the Laplace-Runge-Lenz vector, but the two are, of course, not independent constants of the motion. Indeed, the cross product of Eq. (4) with $m\mathbf{L}$ yields

$$\mathbf{p}\times\mathbf{L} - mk\hat{\mathbf{r}} = m\mathbf{u}\times\mathbf{L}. \tag{10}$$

The left-hand side is the Laplace-Runge-Lenz vector $\mathbf{A}$, so $\mathbf{A} = m\mathbf{u}\times\mathbf{L}$. The three conserved vectors $\mathbf{A}$, $\mathbf{u}$, and $\mathbf{L}$ form a right-handed orthogonal system equivalent to $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, and $\hat{\mathbf{z}}$ after normalization.

As a final comment of pedagogical interest, we present a second approach that may be useful in an elementary discussion of the Coulomb/Kepler problem. We begin with the expression for the energy $E = \frac{1}{2}mv^2 - k/r$. If we use $\mathbf{v}\cdot\hat{\boldsymbol{\theta}} = r\dot{\theta} = L/mr$ to replace $1/r$ by $m\mathbf{v}\cdot\hat{\boldsymbol{\theta}}/L$ in the potential term, we may write E as

$$E = \frac{1}{2}mv^2 - \frac{mk}{L}\mathbf{v}\cdot\hat{\boldsymbol{\theta}}\,. \tag{11}$$

If we complete the square in the velocity, we find

$$E = \frac{1}{2}mu^2 - \frac{mk^2}{2L^2}\,, \tag{12}$$

with $\mathbf{u}$ the same vector as in Eq. (4). It follows that the magnitude of $\mathbf{u}$ must be constant. To prove that this vector is conserved both in magnitude and direction, we must only take a derivative of $\mathbf{u}$ and substitute $d\mathbf{v}/dt = -k\hat{\mathbf{r}}/mr^2$ and $d\hat{\boldsymbol{\theta}}/dt = -\dot{\theta}\hat{\mathbf{r}}$ into the result. The equation of the orbit may then be found as before. This approach does not require any integrations and amounts to a change of gauge from a scalar potential to an effective vector potential description of the problem.
